Abstract:

The creative activity of programming - to be distinguished from coding - is usually taught by examples serving to exhibit certain techniques. It is here considered as a sequence of design decisions concerning the decomposition of tasks into subtasks and of data into data structures. The process of successive refinement of specifications is illustrated by a short but nontrivial example, from which a number of conclusions are drawn regarding the art and the instructions of programming.

Program development by step-wise refinement

1. Introduction

Programming is usually taught by examples. Experience shows that the success of a programming course critically depends on the choice of these examples. Unfortunately, they are too often selected with the prime intent to demonstrate what a computer can do. Instead, a main criterion for selection should be their suitability to exhibit certain widely applicable techniques. Furthermore, examples of programs are commonly presented as finished "products" followed by explanations of their purpose and their linguistic details. But active programming consists of the design of new programs, rather than contemplation of old programs. As a consequence of these teaching methods, the student obtains the impression that programming consists mainly of mastering a language (with all the peculiarities and intricacies so abundant in modern PL's) and relying on one's intuition to somehow transform ideas into finished programs. Clearly, programming courses should teach methods of design and construction, and the selected examples should be such that a gradual development can be nicely demonstrated.

This paper deals with a single example chosen with these two purposes in mind. Some well-known techniques are briefly demonstrated and motivated (strategy of preselection, stepwise construction of trial solutions, introduction of auxiliary data, recursion), and the program is gradually developed in a sequence of refinement steps.

In each step, one or several instructions of the given program are decomposed into more detailed instructions. This successive decomposition or refinement of specifications terminates, when all instructions are expressed in terms of an underlying computer or programming language, and must therefore be guided by the facilities available on that computer or language. The result of the

execution of a program is expressed in terms of data, and it may be necessary to introduce further data for communication between the obtained subtasks or instructions. As tasks are refined, so the data may have to be refined, decomposed, or structured, and it is natural to refine program and data specifications in parallel.

Every refinement step implies some design decisions. It is important that these decision be made explicit, and that the programmer be aware of the underlying criteria and of the existence of alternative solutions. The possible solutions to a given problem emerge as the leaves of a tree, each node representing a point of deliberation and decision. Subtrees may be considered as families of solutions with certain common characteristics and structures. The notion of such a tree may be particularly helpful in the situation of changing purpose and environment to which a program may sometime have to be adapted.

A guideline in the process of step-wise refinement should be the principle to decompose decisions as much as possible, to untangle aspects which are only seemingly interdependent, and to defer those decisions which concern details of representation as long as possible. This will result in programs which are easier to adapt to different environments (languages and computers), where different representations may be required.

The chosen sample problem is formulated at the beginning of paragraph 3. The reader is strongly urged to try to find a solution by himself before embarking on the paper which - of course - presents only one of many possible solutions.

2. Notation

For the description of programs, a slightly augmented Algol 60 notation will be used. In order to express repetition of statements in a more lucid way than by use of labels and jumps, a statement of the form

repeat <statement sequence>

until <Boolean expression>

is introduced, meaning that the statement sequence is to be repeated until the Boolean expression has obtained the value true.

3. The 8-queens problem and an approach to its solution

Given are an 8 x 8 chess board and 8 queens which are hostile to each other. Find a position for each queen (a configuration) such that no queen may be taken by any other queen (i.e. such that every row, column, and diagonal contains at most one queen).

This problem is characteristic for the rather frequent situation where an analytical solution is not known, and where one has to resort to the method of trial and error. Typically, there exists a set A of candidates for solutions, among which one is to be selected which satisfies a certain condition p. Thus, a solution is characterised as an x such that

$$(x \in A) \wedge p(x)$$

A straight-forward program to find a solution is

```
repeat Generate the next element of A
         and call it x
until  p(x) ∨ (no more elements in A);
if p(x) then x = solution
```

The difficulty with this sort of problem usually is the sheer size of A, which forbids an exhaustive generation of candidates on the grounds of efficiency considerations. In the present example, A consists of

$$64 \times 63 \times \dots \times 58 \times 57 \cong 2^{48}$$

elements (board configurations). Under the assumption that generation and test of each configuration consumes $100 \mu\text{s}$, it would roughly take 100 years to find a solution. It is obviously necessary to invent a "shortcut", a method which eliminates a large number of "obviously" disqualified contenders. This strategy of preselection is characterised as follows:

Find a representation of p in the form

$$p = q \wedge r$$

Then let

$$B_r = \{x \mid (x \in A) \wedge r(x)\}$$

Obviously $B_r \subseteq A$. Instead of generating elements of A, only elements of B are produced and tested on condition q instead of p. Suitable candidates for a condition r are those which satisfy the following requirements:

1. B_r is much smaller than A,
2. elements of B_r are easily generated,
3. condition q is easier to test than condition p.

The corresponding program then is

```
repeat Generate the next element of B
        and call it x
until q(x)  $\forall$  (no more elements in B);
if q(x) then x = solution
```

A suitable condition r in the 8-queens problem is the rule that in every column of the board there must be exactly one queen. Condition q then merely specifies that there be at most one queen in every row and in every diagonal, which is evidently somewhat easier to test than p . The set B_r (configurations with one queen in every column) contains "only" $8^8 = 2^{24}$ elements. They are generated by restricting the movement of queens to columns. Thus, all of the above conditions are satisfied.

Assuming again a time of 100 μ s for the generation and test of a potential solution, finding a solution would now consume only 16 seconds. Having a powerful computer at one's disposal, one might easily be content with this gain in performance. If one is less fortunate and is forced to, say, solve the problem by hand, it would take 1.5 hours of generating and testing configurations at the rate of one per second. In this case it might pay to spend some time finding further shortcuts. Instead of applying the same method as before, another one is advocated here which is characterised as follows:

Find a representation of trial solutions x of the form $[x_1, x_2 \dots x_n]$, such that every trial solution can be generated in steps which produce $[x_1]$, $[x_1, x_2]$. . . $[x_1, x_2 \dots x_n]$ respectively. The decomposition must be such that

1. every step (generating x_j) must be considerably simpler to compute than the entire candidate x , and
2. $q(x) \supset q(x_1 \dots x_j)$ for all $j \leq n$,

i.e. a full solution can never be obtained by extending a partial trial solution which does not satisfy the predicate q . On the other hand, however, a partial trial solution satisfying q may not be extensible into a complete solution. This method of stepwise construction of trial solutions therefore requires that trial solutions failing at step j may have to be "shortened" again in order to try different extensions. This technique is called backtracking and may generally be characterised by the program:

```
j := 1;
repeat trystep j;
  if successful then advance else regress
until (j < 1) v (j > n)
```

In the 8-queens example, a solution can be constructed by positioning queens in successive columns starting with column 1 and adding a queen in the next column in each step. Obviously, a partial configuration not satisfying the mutual non-aggression condition may never be extended by this method into a full solution. Also, since during the j -th step only j queens have to be considered and tested for mutual non-aggression, finding a partial solution at step j requires less effort of inspection than finding a complete solution under the condition that all 8 queens are on the board all the time. Both stated criteria are therefore satisfied by the decomposition in which step j consists of finding a safe position for the queen in the j -th column.

The program subsequently to be developed is based on this method; it generates and tests 876 partial configurations before finding a complete solution. Assuming again that each generation and test (which is now more easily accomplished than before) consumes one second, the solution is found in 14.5 minutes, and with the computer taking 100 μ s per step, in 0.09 seconds.

4. Development of the program

We now formulate the step-wise generation of partial solutions to the 8-queens problem by the following first version of a program:

```
variable board, pointer, safe;  
considerfirstcolumn;  
repeat trycolumn;  
    if safe then  
        begin setqueen; considernextcolumn  
        end else regress  
until lastcoldone V regressoutoffirstcol
```

This program is composed of a set of more primitive instructions (or procedures) whose actions may be described as follows:

considerfirstcolumn:

The problem essentially consists of inspecting the safety of squares. A pointer variable designates the currently inspected square. The column in which this square lies is called the currently inspected column. This procedure initialises the pointer to denote the first column.

trycolumn:

starting at the current square of inspection in the currently considered column, move down the column until either a safe square is found, in which case the Boolean variable safe is set to true, or until the last square is reached and is also unsafe, in which case the variable safe is set to false.

setqueen: a queen is positioned onto the last inspected square.

considernextcolumn:

advance to the next column and initialise its pointer of inspection.

regress:

regress to a column where it is possible to move the positioned queen further down, and remove the queens positioned in the columns over which regression takes place. (Note that we may have to regress over at most two columns. Why?)

The next step of program development was chosen to refine the descriptions of the instructions trycolumn and regress as follows:

```
procedure trycolumn;  
repeat advancepointer; testsquare  
until safe V lastsquare  
  
procedure regress;  
  begin reconsiderpriorcolumn  
    if ¬ regressoutoffirstcol then  
      begin removequeen;  
        if lastsquare then  
          begin reconsiderpriorcolumn;  
            if ¬ regressoutoffirstcol then  
              removequeen  
          end  
        end  
      end  
    end  
  end
```

The program is expressed in terms of the instructions

```
considerfirstcolumn  
considernextcolumn  
reconsiderpriorcolumn  
advancepointer  
testsquare      (sets the variable safe)  
setqueen  
removequeen
```

and of the predicates

```
lastsquare  
lastcoldone  
regressoutoffirstcol
```

In order to refine these instructions and predicates further in the direction of instructions and predicates available in common programming languages, it becomes necessary to express them in terms of data representable in those languages. A decision on how to represent the relevant facts in terms of data can therefore no longer be postponed. First priority in decision making is given to the problem of how to represent the positions of the queens and of the square being currently inspected.

The most straight-forward solution (i.e. the one most closely reflecting a wooden chess board occupied by marble pieces) is to introduce a Boolean square matrix with $B[i,j] = \text{true}$ denoting that square (i,j) is occupied. The success of an algorithm, however, depends almost always on a suitable choice of its data representation in the light of the ease in which this representation allows the necessary operations to be expressed. Apart from this, consideration regarding storage requirements may be of prime importance (although hardly in this case). A common difficulty in program design lies in the unfortunate fact that at the stage where decisions about data representations have to be made, it often is still difficult to foresee the details of the necessary instructions operating on the data, and often quite impossible to estimate the advantages of one possible representation over another. In general, it is therefore advisable to delay decisions about data representation as long as possible (but not until it becomes obvious that no realisable solution will suit the chosen algorithm).

In the problem presented here, it is fairly evident even at this stage that the following choice is more suitable than a Boolean matrix in terms of simplicity of later instructions as well as of storage economy:

j is the index of the currently inspected column, (x_j, j) is the coordinate of the last inspected square, and the position of the queen in column $k < j$ is given by the coordinate pair (x_k, k) of the board. Now the variable declarations for pointer and board are refined into:

```
integer j (0 ≤ j ≤ 9)
integer array x[1:8] (0 ≤ xi ≤ 8)
```

and the further refinements of some of the above instructions and predicates are expressed as

```
procedure considerfirstcolumn;
  begin j := 1; x[1] := 0 end

procedure considernextcolumn;
  begin j := j+1; x[j] := 0 end

procedure reconsiderpriorcolumn; j := j-1

procedure advancepointer;
  x[j] := x[j] + 1

Boolean procedure lastsquare;
  lastsquare := x[j] = 8

Boolean procedure lastcoldone;
  lastcoldone := j > 8

Boolean procedure regressoutoffirstcol;
  regressoutoffirstcol := j < 1
```

At this stage, the program is expressed in terms of the instructions

```
testsquare
setqueen
removequeen
```

As a matter of fact, the instructions setqueen and removequeen may be regarded as vacuous, if we decide that the procedure testsquare is to determine the value of the variable safe solely on the grounds of the values $x_1 \dots x_{j-1}$ which completely represent the positions of the $j-1$ queens so far on the board. But unfortunately the instruction testsquare is the one most frequently executed, and it is therefore the one instruction where considerations of efficiency are not only justified but essential for a good solution of the problem. Evidently a version of testsquare expressed only in terms of $x_1 \dots x_{j-1}$ is inefficient at best. It should be obvious that testsquare is executed far more often than setqueen and removequeen. The latter procedures are executed whenever the column (j) is changed (say m times), the former whenever a move to the next square is undertaken (i.e. x_j is changed, say n times). However, setqueen and removequeen are the only procedures which affect the chessboard. Efficiency may therefore be gained by the method of introducing auxiliary variables $V(x_1 \dots x_j)$ such that

1. whether a square is safe can be computed more easily from $V(x)$ than from x directly (say in u units of computation instead of ku units of computation)
2. the computation of $V(x)$ from x (whenever x changes) is not too complicated (say of v units of computation)

The introduction of V is advantageous (apart from considerations of storage economy), if

$$n(k-1)u > mv \quad \text{or} \quad \frac{n}{m} (k-1) > \frac{v}{u}$$

i.e. if the gain is greater than the loss in computation units.

A most straight-forward solution to obtain a simple version of testsquare, is to introduce a Boolean matrix B such that $B[i,j] = \text{true}$ signifies that square (i,j) is not taken by another queen. But unfortunately, its recomputation whenever a new queen is removed (v) is prohibitive (why?) and will more than outweigh the gain.

The realization that the relevant condition for safety of a square is that the square must neither lie in a row nor in a diagonal already occupied by another queen, leads to a much more economic choice of V . We introduce Boolean arrays a , b , c with the meanings

- $a_k = \text{true}$: no queen is positioned in row k
- $b_k = \text{true}$: no queen is positioned in the $/$ -diagonal k
- $c_k = \text{true}$: no queen is positioned in the \backslash -diagonal k

The choice of the index ranges of these arrays is made in view of the fact that squares with equal sum of their coordinates lie on the same $/$ -diagonal, and those with equal difference lie on the same \backslash -diagonal. With row and column indices from 1 to 8, we obtain

Boolean array $a[1:8]$, $b[2:16]$, $c[-7:7]$

Upon every introduction of auxiliary data, care has to be taken of their correct initialization. Since our algorithm starts with an empty chess-board, this fact must be represented by initially assigning the value true to all components of the arrays a , b , and c .

We can now write

```
procedure testsquare;  
  safe := a[x[j]]  $\wedge$  b[j+x[j]]  $\wedge$  c[j-x[j]]  
  
procedure setqueen;  
  a[x[j]] := b[j+x[j]] := x[j-x[j]] := false  
  
procedure removequeen;  
  a[x[j]] := b[j+x[j]] := c[j-x[j]] := true
```

The correctness of the latter procedure is based on the fact that each queen currently on the board had been positioned on a safe square, and that all queens positioned after the one to be removed now, had already been removed. Thus, the square to be vacated becomes safe again.

A critical examination of the program obtained so far reveals that the variable $x[j]$ occurs very often, and in particular at those places of the program which are also executed most often. Moreover, examination of $x[j]$ occurs much more frequently than reassignment of values to j . As a consequence, the principle of introduction of auxiliary data can again be applied to increase efficiency: a new variable

integer i

is used to represent the value so far denoted by $x[j]$. Consequently

```
x[j] := i
```

must always be executed before j is increased, and

```
i := x[j]
```

after j is decreased. This final step of program development leads to the reformulation of some of the above procedures as follows:

```
procedure testsquare;  
    safe := a[i]  $\wedge$  b[i+j]  $\wedge$  c[i-j]  
procedure setqueen;  
    a[i] := b[i+j] := c[i-j] := false  
procedure removequeen;  
    a[i] := b[i+j] := c[i-j] := true  
procedure considerfirstcolumn;  
    begin j := 1; i := 0 end  
procedure advancepointer; i := i+1  
procedure considernextcolumn;  
    begin x[j] := i; j := j+1; i := 0 end  
Boolean procedure lastsquare;  
    lastsquare := i = 8
```

The final program, using the procedures

```
testsquare  
setqueen  
regress  
removequeen
```

and with the other procedures directly substituted, now has the form

```
j := 1; i := 0;  
repeat  
    repeat i := i+1; testsquare  
    until safe  $\vee$  (i=8);  
    if safe then  
        begin setqueen; x[j] := i; j := j+1; i := 0  
        end else regress  
until (j > 8)  $\vee$  (j < 1);  
if j > 8 then PRINT(x) else FAILURE
```

It is noteworthy that this program still displays the structure of the version designed in the first step. Naturally other, equally valid solutions can be suggested and be developed by the same method of step-wise program refinement. It is particularly essential to demonstrate this fact to students. One alternative solution was suggested to the author by E.W. Dijkstra. It is based on the view that the problem consists of a step-wise extension of the board by one column containing a safely positioned queen, starting with a null-board and terminating with 8 columns. The process of extending the board is formulated as a procedure, and the natural method to obtain a complete board is by recursion of this procedure. It can easily be composed of the same set of more primitive instructions which were used in the first solution.

```
procedure Trycolumn(j);  
  begin integer i; i := 0;  
    repeat i := i+1; testsquare  
      if safe then  
        begin setqueen; x[j] := i;  
          if j < 8 then Trycolumn (j+1);  
          if  $\neg$  safe then removequeen  
        end  
      until safe  $\vee$  (i=8)  
  end
```

The program using this procedure then is

```
Trycolumn(1);  
if safe then PRINT(x) else FAILURE
```

(Note that due to the introduction of the variable i local to the recursive procedure, every column has its own pointer of inspection i.

As a consequence, the procedures

```
testsquare  
setqueen  
removequeen
```

must be declared locally within Trycolumn too, because they refer to the `i` designating the scanned square in the current column.)

5. The generalised 8-queens problem

In the practical world of computing, it is rather uncommon that a program, once it performs correctly and satisfactorily, remains unchanged forever. Usually its users discover sooner or later that their program does not deliver all the desired results, or worse, that the results requested were not the ones really needed. Then either an extension or a change of the program is called for, and it is in this case where the method of step-wise program design and systematic structuring is most valuable and advantageous. If the structure and the program components were well chosen, then often many of the constituent instructions can be adopted unchanged. Thereby the effort of re-design and reverification may be drastically reduced. As a matter of fact, the adaptability of a program to changes in its objectives (often called maintainability) and to changes in its environment (nowadays called portability) can be measured primarily in terms of the degree to which it is neatly structured.

It is the purpose of the subsequent chapter to demonstrate this advantage in view of a generalization of the original 8-queens problem and its solution through an extension of the programs components introduced before.

The generalised problem is formulated as follows:

Find all possible configurations of 8 hostile queens on an 8x8 chess board, such that no queen may be taken by any other queen.

The new problem essentially consists of two parts, namely of

1. finding a method to generate further solutions, and
2. determining whether all solutions were generated or not.

It is evidently necessary to generate and test candidates for solutions in some systematic manner. A common technique is to find an ordering of candidates and a condition to identify the last candidate. If an ordering is found, the solutions can be mapped onto the integers. A condition limiting the numeric values associated with the solutions then yields a criterion for termination of the algorithm, if the chosen method generates solutions strictly in increasing order.

It is easy to find orderings of solutions for the present problem. We choose for convenience the mapping

$$M(x) = \sum_{j=1}^8 x_j \cdot 10^{j-1}$$

An upper bound for possible solutions is then

$$M(x_{\max}) = 88888888$$

and the "convenience" lies in the circumstance that our earlier program generating one solution generates the minimum solution which can be regarded as the starting point from which to proceed to the next solution. This is due to the chosen method of testing squares strictly proceeding in increasing order of $M(x)$

starting with 00000000. The method for generating further solutions must now be chosen such that starting with the configuration of a given solution, scanning proceeds in the same order of increasing M, until either the next higher solution is found, or the limit is reached.

6. The extended program

The technique of extending the two given programs finding a solution to the simple 8-queens problem is based on the idea of modification of the global structure only, and of using the same building blocks. The global structure must be changed such that upon finding a solution the algorithm will produce an appropriate indication - e.g. by printing the solution - and then proceed to find the next solution until it is found or the limit is reached. A simple condition for reaching the limit is the event when the first queen is moved beyond row 8, in which case regression out of the first column will take place. These deliberations lead to the following modified version of the nonrecursive program:

```
considerfirstcolumn;
  repeat trycolumn;
    if safe then
      begin setqueen; considernextcolumn;
        if lastcoldone then
          begin PRINT(x); regress
        end
      end else regress
    until regressoutoffirstcol
```

Indication of a solution being found by printing it now occurs directly at the level of detection, i.e. before leaving the repetition clause. Then the algorithm proceeds to find a next solution whereby a short-cut is used by directly regressing to the prior column; since a solution places one queen in each row, there is no point in further moving the last queen within the eighth column.

The recursive program is extended with even greater ease following the same considerations:

```
procedure Trycolumn(j);  
begin integer i;  
  <declarations of procedures testsquare, advancequeen,  
  setqueen, removequeen, lastsquare>  
  i := 0;  
  repeat advancequeen; testsquare;  
    if safe then  
      begin setqueen; x[j] := i;  
        if  $\neg$  lastcoldone then Trycolumn(j+1) else PRINT(x);  
        removequeen  
      end  
    until lastsquare  
end
```

The main program starting the algorithm then consists (apart from initialization of a, b, and c) of the single statement

```
Trycolumn(1)
```

In concluding, it should be noted that both programs represent the same algorithm. Both determine 92 solutions in the same order by testing squares 15720 times. This yields an average of 171 tests per solution; the maximum is 876 tests for finding a next solution (the first one), and the minimum is 8.

(Both programs coded in the language Pascal were executed by a CDC 6400 computer in less than one second).

7. Conclusions

The lessons which the described example was supposed to illustrate can be summarised by the following points:

1. Program construction consists of a sequence of refinement steps. In each step a given task is broken up into a number of subtasks. Each refinement in the description of a task may be accompanied by a refinement of the description of the data which constitute the means of communication between the subtasks. Refinement of the description of program and data structures should proceed in parallel.
2. The degree of modularity obtained in this way will determine the ease or difficulty with which a program can be adapted to changes or extensions of the purpose or changes in the environment (language, computer) in which it is executed.
3. During the process of stepwise refinement, a notation which is natural to the problem in hand should be used as long as possible. The direction in which the notation develops during the process of refinement is determined by the language in which the program must ultimately be specified, i.e. with which the notation ultimately becomes identical. This language should therefore allow us to express as naturally and clearly as possible the structures of program and data which emerge during the design process. At the same time, it must give guidance in the refinement process by exhibiting those basic features and structuring principles which are natural to the machine by which programs are supposed to be executed.

It is remarkable that it would be difficult to find a language that would meet these important requirements to a lesser degree than the one language still used most widely in teaching programming: Fortran.

4. Each refinement implies a number of design decisions based upon a set of design criteria. Among these criteria are efficiency, storage economy, clarity and regularity of structure. Students must be taught to be conscious of the involved decisions and to critically examine and to reject solutions, sometimes even if they are correct as far as the endeffect is concerned; they must learn to weigh the various aspects of design alternatives in the light of these criteria. In particular, they must be taught to revoke earlier decisions, and to back up, if necessary even to the top. Relatively short sample problems will often suffice to illustrate this important point; it is not necessary to construct an Operating System for this purpose.
5. The detailed elaborations on the development of even a short program form a long story, indicating that careful programming is not a trivial subject. If this paper has helped to dispell the wide-spread belief that programming is easy as long as the programming language is powerful enough and the available computer is fast enough, then it has achieved one of its purposes.
